Header: Misarticulations and word identification

The influence of misarticulations on children’s word identification and processing.

Breanna I. Krueger, Holly L. Storkel and Utako Minai

University of Kansas

Abstract

Purpose: The purpose of the present studies was to determine how children's identification and processing of misarticulated words was influenced by substitution commonness.

Method: Sixty-one typically-developing preschoolers across three experiments heard accurate productions of words (e.g. "leaf"), words containing common substitutions (e.g. "weaf"), and words containing uncommon substitutions (e.g. "yeaf"). On each trial, preschoolers chose between a real object picture (e.g. a leaf) and a non-object (e.g. an anomalous line drawing). Accuracy and processing were measured using MouseTracker and eye-tracking.

Results: Overall, children chose real objects significantly more when presented with accurate productions (e.g. "leaf") than misarticulated productions (e.g. "weaf" or "yeaf"). Within misarticulation conditions, children chose real objects significantly more when hearing common misarticulations (e.g. "weaf") than uncommon misarticulations (e.g. "yeaf"). Preschoolers identified words significantly faster and with greater certainty in accurate conditions than misarticulated conditions.

Conclusions: The results of the present studies indicate the commonness of substitutions influences children's identification of misarticulated words. Children hear common substitutions more frequently, and therefore, were supported in their identification of these words as real objects. The presence of substitutions, however, slowed reaction time when compared to accurate productions.

Introduction

Every spoken utterance is characterized by elements of variability caused by a variety of sources. These sources range from subtle, mechanical differences in oral motor movement (e.g. phonetic variability), to the substitution of entire phonemes as a result of accent, or developmental misarticulations (e.g. phonemic variability). The ability to attend to the intended speech target despite such inconsistency plays a key role in children’s language acquisition. Children are capable of, and, in fact, quite good at understanding words from the input they receive; however, different types of variability seem to influence the perception and processing of words in different ways.

Speech Variability

There are two types of variability produced by speakers that may impact speech perception. Phonetic variability occurs in every utterance of a phoneme--each production presents with unique spectral characteristics. Phonetic variability is variability that does not trigger a change in meaning. For example, the [t^h] in “top” is different from the [t] in “stop” in terms of aspiration, yet both are perceived as the underlying phoneme /t/ in English. The phonetic context of the cluster /st/ in “stop” reduces the degree of aspiration and voice-onset time as a result of coarticulation, which produces a source of phonetic variability (Klatt, 1975). Although this type of variability is predictable from context, and arrives from many sources (e.g. phonotactics, accent), children still acquire words from their environment, thanks to the ability to encode acoustic information into phonemic categories (Liberman, Harris, Hoffman, & Griffith, 1957; Liberman, Ingemann, Lisker, Delattre, & Cooper, 1959).

A second form of speech variability is phonemic variability. Phonemic variability occurs when a single phoneme is substituted for another. Phonemic variability occurs in cases where the

speaker is, for whatever reason, unable to produce the target phoneme in the phonological system. In some cases, the phoneme may not occur in the speaker's first language, thus a substitution is made (i.e. Arabic does not have a /p/ as a phoneme, thus a /b/ is often used in its place). Depending on the type of change, phoneme changes may trigger a change in meaning. For example, when a child produces a developmental misarticulation such as /w/ for /l/, the intended message may be misunderstood. If a child says "wight" instead of "light", this triggers a change in meaning for the listener, since the substitution is a different real word, "white."

Perception of variability

The perception of speech variability, particularly phonetic variability, has been well-studied in adults. Generally, adult listeners process phonetic variability with little difficulty. The ease of interpretation can likely be attributed to having mature phonological representations and lifelong experience with many forms of variability. Clopper and Pisoni (2004) found that adults who were exposed to a variety of dialects as children accurately categorized the dialects into the region in which the dialect is commonly found as adult listeners. This finding suggests that adults draw upon experiences with speech variability from experiences as children to identify regionally specific locations of dialect types, and use that experience to comprehend and understand words with phonetic variability. This finding may suggest that children have the capability to be flexible in their interpretation of speech sound differences, and may use top-down information, such as knowledge of dialect, to assist in their interpretation. In addition to drawing upon these experiences, evidence has shown that adults use top-down lexical and pre-lexical cues to assist with accommodation of variability, as in the case of ambiguous or degraded productions (McClelland, Mirman, & Holt, 2006). Adults use word-level information to infer the intended target, which allows them to categorize the different phonetic variations of each

phoneme. Each of these processes involve on-line learning and adaptation on the part of the perceiver, which slows processing time considerably (McClelland et al., 2006).

Previous research investigating children’s perception of phonological and phonetic variation are largely focused on how these types of variability impact children’s identification of words and how that process is attuned to the word-learning process. This research suggests that very young children perceive words with a level of phonological detail and segmentation ability that assists them in their recognition of words (Swingley, 2005; Swingley, 2009). At approximately 19 months, toddlers acquire the ability to accommodate different dialects of English, such as Jamaican-accented speech (Best, Tyler, Gooding, et al., 2009). According to Best et al. (2009), this skill appears to emerge sometime after age 15 months, as younger children produce more phonetic approximations of auditory stimuli than older children; older children, on the other hand, identify the words as variable productions, and produce them in their own dialect. This level of perceptual ability assists children in learning new words from their environment, and from a variety of sources, but also points to a level of meta-awareness of the speech sound system itself. Other research has suggested that, by the age of 4, children phonetically imitate different dialects and accents when given auditory stimuli, but by the age 7, children produced the accented productions in their own dialects, rather than making a phoneme-by-phoneme imitation (Bent, 2014). In each of these studies, the researchers suggested that their findings may be the result of 4-year-olds being in a period of lexical acquisition, and this flexibility is, necessarily, a requisite to word learning (Bent, 2014; Best et al. 2009). Children must be able to segment words into phonemes, evaluate whether they are part of a new word, and then access possibilities that match what is already existing in the lexicon to make their decision. This ability appears to be involved in the process of word learning. In fact, Altvater-Mackensen

and Mani (2013) found that misarticulated words produce cascaded activation of semantically related words in 2 year-olds. That is, a misproduction of the word “nurse” would produce cascaded lexical activation of the semantically-related word “doctor,” suggesting that even at age 2, children are flexible in their acceptance of variable speech. The findings of these studies show that children across the preschool years are sensitive to both phonetic and phonemic variability, and that their awareness is a key element in the process of word and sound learning.

In the acquisition of their native language, children must be able to segment words in to phonemic units in order to establish whether a word is known, or unknown; however, these units must have some flexibility in terms of children’s acceptance in order to accommodate speech variability that they are inevitably exposed to whether it is the result of dialect, accent, or misarticulation. Creel (2012) examined children’s identification and processing of words containing phoneme substitutions. This study targeted children’s identification and processing of words containing phoneme substitutions as either real words or as new words. The substitutions were created by shifting the typically produced phoneme by phonological features. For example, “fish” is shifted to “fesh” where the vowel /ɪ/ is shifted downward one step in the vowel space to /ɛ/, and the /g/ in “grape” is shifted to “krape” where there is a change in voicing from /g/ to /k/. These substitutions varied in terms of feature distance from the target (e.g. /greɪp/ → /kreɪp/ is “close” and /greɪp/ to /treɪp/ is “far”) to determine if the feature distance was an influential factor in children’s identification and processing of these words. The results showed that as feature distance increased, children identified words as real objects significantly less often than “close” or accurate productions. Furthermore, *any* presence of variability slowed children’s processing. Creel (2012) also included an analysis of children’s eye-gaze and found that fixations on the target occurred later when hearing altered productions of words, but there was no difference in

on-line eye-gaze fixation latency between “close” feature changes and “far” feature changes within shifted stimuli conditions. Both atypical productions yielded slowed and reduced looks to the target object. These results suggest that children are largely biased toward selecting real objects, but their processing is adversely affected, and they seem to consider other objects longer when hearing shifted stimuli than accurately-produced stimuli.

The results of Creel (2012) suggest that children are sensitive to phonemic variability, but processing is slowed. However, the stimuli in that study were created by altering phonological features of the phonemes, such as voicing and place, systematically. In other words, these changes were not developed to mimic any real-world model with which a child may have experience. However, children *do* have experience with phonemic variability: the misarticulations they hear from their peers and produce themselves. Most children will produce phonemic substitutions as they develop their ability to produce the sounds of their first language. These substitutions are typically the same across children, according to developmental normative data (Smit, Hand, Freilinger, Bernthal, & Bird, 1990). This raises the question of whether common misarticulations that are routinely heard in the environment (e.g., “wight” for “light”) are processed differently than uncommon misarticulations that are rarely, if ever, encountered in the environment (e.g., “yight” for “light”) as well as whether these misarticulated productions are processed differently than accurate productions (e.g., “light” for “light”). The investigation of this question allows for consideration of misarticulations as part of the ambient linguistic input that may interact with children’s perception and processing of words, which, in turn, allows for an examination of the role of linguistic input impacting the development of word perception and processing.

The present series of experiments investigated whether children's experience with substitution types impacted their identification and processing of words. Experiment 1 used MouseTracker software (Freeman & Ambady, 2010) and a two-alternative forced-choice selection task to examine whether preschool-aged children identify and process words with common (e.g., 'weaf' for "leaf") or uncommon misarticulations (e.g., "yeaf" for "leaf") in the same way as accurate productions (e.g., "leaf" for "leaf"). In Experiment 1, the speaker of the stimuli was an adult, to control for substitution type, duration of the tokens and to ensure high-quality, consistent recording conditions. Experiment 2 is a replication of Experiment 1, but with tokens produced by children who misarticulated naturally. This experiment only included accurate productions and common misarticulations due to the rarity of uncommon misarticulations in naturally produced speech. Finally, Experiment 3 is a replication of Experiment 1 using an eye-tracker for a closer examination of children's processing of accurate and misarticulated words. Eye-tracking allowed for a more fine-grained analysis of children's on-line processing and eye-gaze behavior, as well as a comparison between the MouseTracking and eye-tracking technologies. Across experiments, the dependent variables were proportion of real-object selections (when given a choice between a real object and a novel object), reaction time, and area under the curve for mouse trajectories (Experiment 1 and 2) or looking patterns for eye gaze (Experiment 3). Independent variables were word types: accurate production, common misarticulation and uncommon misarticulation.

Experiment 1

Research questions

The present study investigated children's identification and processing of words containing misarticulations to determine if frequent exposure to this form of variability

1
2
3 influenced children’s real-object responses. To this end, we manipulated the commonness of the
4
5 substitution type and compared children’s identification of these words as real objects or novel
6
7 objects. Our research questions were as follows:
8
9

- 10
- 11 1) Do children select real objects more often for accurately produced words than
- 12 words containing substitutions?
- 13
- 14
- 15 2) Do children select the real objects for accurately-produced words more quickly
- 16 and with more direct mouse trajectories than for misarticulated words?
- 17
- 18
- 19 3) When words are misarticulated, do children select real objects for common
- 20 misarticulations more frequently than for those with uncommon misarticulations?
- 21
- 22
- 23 4) When words are misarticulated, do children select real objects for common
- 24 misarticulations more quickly and with more direct eye trajectories than those
- 25 with uncommon misarticulations?

- 31

32 **Methods**

33

34 **Participants.** Twenty-three monolingual children ($M = 5$ years, 0 months; $SD = 0$ years,
35 3 months; range 4 years, 0 months-5 years, 11 months; 9 females, 11 males) were recruited from
36 local preschools to participate in Experiment 1. Twenty children were Caucasian; two children
37 were Multiracial; 1 child was Asian or Pacific Islander. Three additional participants were
38 excluded (2 for failing the hearing screening; 1 for scheduling conflicts). Parents signed
39 informed consent statements and completed case history questionnaires that included
40 developmental and health questions to be answered about their child. In these questionnaires,
41 parents were asked to complete a rating of their child’s frequency around other children who
42 misarticulate. We used a visual analog scale for this estimation (McCormack, Horne, &
43 Sheather, 1988; Wewers & Lowe, 1990; Wuyts, De Bodt, & Van de Heyning, 1999). Parents

marked along a 100mm line how much their children were around other children who misarticulate. Their marks were then measured to give a value out of 100. Parents rated their children's exposure to children who misarticulate to be 58 on average ($SD = 25$ range 23-100). In addition, by recruiting from preschools, we ensured that participants had exposure to other children their age, increasing the likelihood that they frequently heard misarticulated speech that occurs in typical development. To participate in the study, children were required to be monolingual English speaking children, who were typical in terms of hearing, receptive language and articulation. Hearing was assessed using the American Speech-Language-Hearing audiologic screening protocol (1997). Each child completed the Peabody Picture Vocabulary Test, 4th edition (PPVT-4), to measure his or her receptive vocabulary (Dunn & Dunn, 2012). Participants' standard scores were 114, on average ($SD=9$, range 96-129), indicating typical receptive language development (standard scores between 85-115 were considered to be within the expected range).

For articulation, participants were assessed using the Goldman-Fristoe Test of Articulation-2 (GFTA-2). All participants were typically developing in terms of articulation with all standard scores falling within the expected range of 85-115 ($M = 111$; $SD=4$, range 99-118). The stimuli for the present study were constructed using late-acquired sounds and consonant clusters so children had a greater likelihood of having heard these sounds misarticulated. Previous research identifies "late" sounds as those that are the last to be acquired in typical phonological development (Bleile, 2006; Shriberg, Gruber, & Kwiatkowski, 1994; Smit et al., 1990). Thus, each child's production of late acquired sounds (/θ, ð, s, z, l, ɹ, ʃ, tʃ/) was examined in five additional words selected from the Phonological Knowledge Protocol (PKP) (Dinnsen & Gierut, 2008). The late-acquired sounds were elicited in word-initial position in five different

words that varied the following vowel. The procedure was the same as the GFTA-2, where children orally respond to a series of pictures. Their responses were phonetically transcribed and any errors were noted. The phonemes targeted in the present experiments were examined for the participants overall. These phonemes are typically acquired later, on average, but can be acquired earlier as shown in our participants. The results indicated that subjects produced some errors on experimental targets, but overall were highly accurate ($M=91\%$, $SD=8\%$, Range= 70%-100%). This level of accuracy was expected given the age and articulation skills of the participants. Although some children produced articulation errors, an analysis of the experimental data from the children who produced articulation errors showed no significant differences from the children who produced sounds accurately.

Materials

Auditory Stimuli. Auditory stimuli consisted of 12 target words selected to be picturable, and frequent in the child’s lexicon, as shown in Table 1 (Storkel & Hoover, 2010). The real words had a log frequency at or above 1 and ranged between 1 and 4 ($M=2.64$, $SD=0.65$). Target words were selected to begin with late-acquired sounds (Smit et al., 1990) to ensure that children had maximal exposure to misarticulations associated with these phonemes. Common misarticulations (see Table 1) were selected by examining a cross-sectional study of children’s substitution types from Smit (1993) in the 4.5-5 year age range (Smit et al., 1990; Smit, 1993). A phoneme was chosen as a common substitute if it was the most common substitute for the target phoneme (e.g. the most common substitute for target phoneme /l/ in initial position was /w/) from the tables in Smit (1993) for the 4 to 5 year-old age range. The most common substitute was selected only if the resulting word was not a real word. In this case, the next most common substitute would be selected.

Uncommon substitutes (Table 1) were chosen by examining both the number and type of features (Chomsky & Halle, 1968). First, the change from accurate to common substitute was compared to determine the number of distinctive features they differed by. Then the type of place-voice-manner features were noted. This was then used to generate other substitutes that were similar in the number and type of feature differences. These candidates were compared to the typical substitution patterns as reported by Smit (1993). Substitutes that never occurred or that were classified as “rare” were selected for the uncommon substitute. This method allowed for the number and type of feature differences to be matched across common and uncommon substitutes. This matching was necessary because Creel (2012) already demonstrated that the number of feature differences impacted processing. In this way, our common and uncommon substitutes differed only in the frequency of the substitution pattern, and not in their closeness to the accurate target.

An additional factor that potentially could influence children’s selections was the possibility that, although features were controlled, the two substitutes were phonetically similar to the accurate phonemes. In order to ensure that this was not a factor, we determined the confusability between the accurate initial phoneme, and each misarticulated phoneme, in accordance with the procedures in Han, Storkel, Lee & Cox (2016). From the tables in Wang & Bilger (1973), we found the proportion of times each accurate phoneme was confused with the misarticulated phoneme. These values are shown as a proportion in Table 1. In terms of the mean proportions, it appears that common substitutes were more often confused with the accurate phoneme than uncommon substitutes; however, a paired samples t-test between common and uncommon word lists showed no significant difference [$t(10)=1.65, p=0.13$] between the two word lists, which suggested that confusability between common and uncommon word lists was

controlled.

INSERT TABLE 1 HERE

Auditory stimuli were recorded by the first author, a native speaker of a Midwestern dialect of English, in an anechoic chamber using a Marantz PMD671 solid-state digital recorder. Words were recorded three times each in the carrier phrase “Look at the _____” to ensure similar intonation and to control for listing effects. The words were then extracted from the carrier phrase using Praat sound editing software, with 250ms of silence embedded at the onset and offset of each word (Boersma & Weenink, 2013). The mean intensity of all items together was measured to be 65 dB, then each word was scaled to a peak intensity of 65 dB to match. The duration of the words were measured and compared to find tokens that were similar in duration across the three stimuli conditions (see Table 1, Supplemental Materials).

Visual stimuli. Twelve black-and-white line drawings were selected from Microsoft Clipart and the Snodgrass and Vanderwart (1980) standardized set of pictures to match each production of the accurate words. Twenty-four pictures were black-and-white line drawings of anomalous objects from Kroll and Potter (1984) (see Table 2, Supplemental Materials). Each misarticulated word was matched with a unique non-object to reduce the possibility of a mutual exclusivity violation (Markman & Wachtel, 1988; Merriman, Bowman, & MacWhinney, 1989). In other words, if children identified a "weaf" as being the non-object, they may not also call a "yeaf" that same novel object. This control reduced the likelihood of introducing a potential experimental confound.

Characteristics of the nonobjects were available from Kroll and Potter (1984) and Storkel and Adlof (2009). Storkel and Adlof (2009) collected data from adults for all of the nonobjects and from children for only a subset of the nonobjects. Since the current study was

1
2
3 conducted with children, only the subset of nonobjects with child data were used (see Table 2,
4 Supplemental Materials). From this subset, nonobjects were eliminated based on adult object-
5 likeness ratings from Kroll and Potter (1984). This value was obtained by asking adults and
6 children to rate on a 7-point scale the degree to which the non-object resembled a real object
7 (where 1 indicated "nothing like a real object" and 7 indicated "looks like a real object") (Kroll &
8 Potter, 1984). Nonobjects with ratings of 6 and above were removed so that the remaining
9 nonobjects would be less likely to be confused with real objects.
10
11
12
13
14
15
16
17
18
19

20 Child semantic set size and child strength of the first neighbor from Storkel and Adlof
21 (2009) were then used to further reduce the pool and create two sets of matched nonobjects.
22 Child semantic set size was the number of different neighbors reported by at least two child
23 participants (Storkel & Adlof, 2009). The child strength of the first neighbor was calculated by
24 dividing the number of children who responded with this particular neighbor by the total number
25 of child participants. Nonobjects with many semantic neighbors (i.e., 9 or more) and relatively
26 weak first neighbors (i.e., strength of 0.20 or less) were selected so that children would not have
27 a strong real object interpretation of the nonobjects. The 24 selected nonobjects were then
28 divided into two sets of 12 that were matched in terms of child set size, strength of the first
29 semantic neighbor and object likeness. Each of these pictures were cropped and resized to 144 x
30 144 pixels to control for the size of the selection area in the mouse-tracking software. Each set of
31 pictures was paired with the common or uncommon substitutions, with the exact pairing varying
32 across participants. This matching was done to ensure that children had a unique, free choice for
33 each word they heard. By having an individual possibility for each word, we allowed for children
34 to identify that each misarticulated word was potentially a novel object without violating
35 principles of mutual exclusivity (Markman & Wachtel, 1988; Merriman, Bowman &

MacWhinney, 1989). If only one novel object per set were used, children may have been influenced to choose the real object, when they otherwise would not have done so, because they already identified another misarticulated word in the set as the novel object.

Experimental Design

Experimental Control. Each pair of audio tokens (accurate and common substitute; accurate and uncommon substitute) were matched with a visual display of a real object and a nonobject (e.g. chick and “nonobject 75”; chick and “nonobject 79”) to create 4 trials for a given stimulus triplet (chick-fick-shick). The 4 trials were distributed across two blocks so that the two repetitions of the accurate production (chick) occurred in different blocks and the repetition of the visual display (e.g. chick and “nonobject 75”) occurred in different blocks. See Table 3 of the supplemental materials for details.

Procedures

Testing took place in a quiet room within the preschools that the participants attended in 1 or 2 sessions, depending on the attention of each child. Stimuli were presented on a Dell Latitude D610 PC Laptop with external speakers, a 17.25” x 13.25” mousepad, and a single-button optical mouse. The picture and audio stimuli were presented using MouseTracker software (Freeman & Ambady, 2010). MouseTracker was used because previous research suggests it has the capability to capture processing differences in adult (Freeman, Dale & Farmer, 2011) and child populations (Berteletti & Lucangeli, 2012; Cargill, Farmer, Schwade, Goldstein & Spivey, 2004) that are similar to those found in eye-tracking studies. Additionally, MouseTracker required minimal setup and was as portable as a laptop computer, thus allowing for mobile data collection at preschool sites. Although this technology has not previously been used extensively in children, our pilot data suggested that children as young as age 4 were

capable of acclimating to mouse use in a very short time—within 5 trials. We ensured that the task was attainable by children by providing large icons placed at a maximal distance from one another (Hourcade, Bederson & Druin, 2004).

Parents provided informed consent statements, and verbal assent was obtained from preschoolers. Once children assented to the procedure, they were evaluated for hearing, language and articulation. The experimental study included a brief training session of five trials to acclimate the child to the experimental task in which children were instructed, “Click on the picture that matches what you hear.” Then testing proceeded with the experimental trials. If the child was slow or hesitant in their movement of the mouse, he or she was instructed, “Be sure to move the mouse straight and fast!” Once the experimental trials began, all corrective feedback ceased.

INSERT FIGURE 1 HERE

Children were shown a screen with a "start" button (see Figure 1). They were instructed to click on the start button to hear the word. After clicking the start button, a 250 ms interstimulus interval of silence was heard, and then the word was presented aurally with two pictures. One picture was a non-object, and the other was a real object picture. The child's task was to click the mouse cursor on the picture that corresponded to the word. After the child clicked the picture, a new start button would appear for the next trial. On average, children completed the task in approximately 10 minutes.

Data Analysis

Each output file was processed using the Mousetracker Analyzer software (Freeman & Ambady, 2010). We extracted the proportion of real object choices, the mean reaction time to the real object, and the mean area under the curve when selecting the real object. These

1
2
3 measurements were separated by independent variable types: common speech sound substitutes
4
5 (e.g. “weaf”), uncommon speech sound substitutes (e.g. “yeaf”) and accurate production (e.g.,
6
7 “leaf”). Accurate productions were responded to twice: once with the visual display used for the
8
9 common substitute and once with the visual display for the uncommon substitute. Thus,
10
11 dependent variables were computed separately for each display.
12
13
14

15 The proportion of real object selections was calculated for each condition by dividing the
16
17 number of real object selections by the total number of trials (12) for each condition. Reaction
18
19 time was measured by the software as the time between the "start" click and the response click of
20
21 the mouse. The mean area under the curve was calculated by considering each mouse path as a
22
23 line on a coordinate grid. A line of best fit was calculated to find the mean line of all the mouse
24
25 paths for a condition. Then the area under this line was calculated. A larger area indicates a more
26
27 curved line, suggesting greater uncertainty than a smaller area, or more direct line from start to
28
29 picture selection. Mean area under the curve provided information about the participants’ degree
30
31 of attraction to the unselected alternative (Freeman & Ambady 2010, Quetard et al., 2016). A
32
33 higher area under the curve measurement suggested that mouse behavior was driven toward the
34
35 alternate before ultimately making a selection. Reaction time and area under the curve were only
36
37 analyzed for trials where the child selected the real object. Real object responses were analyzed
38
39 because children, overall, selected the real object for the majority of trials in each condition
40
41 regardless of the auditory token they heard. Furthermore, the measures of processing were more
42
43 important on real-object selection trials, because they reflected any indecision before finally
44
45 making the targeted response. Restricting analysis to real object choices allowed for a
46
47 comparison of speed and mouse trajectory to the same response outcome. Nonobject selections
48
49 were examined in a separate analysis, but yielded nonsignificant results, and have henceforth
50

59
60

been excluded from the present discussion.

Results

INSERT FIGURE 2 HERE

The proportion of real object selections were compared using a 2 Word Type (Accurate vs. Substitute) x 2 Substitute Type (Common vs. Uncommon) repeated measures ANOVA (Figure 2). A significant main effect of Word Type was found [$F(1,19)=20.43$, $p<.001$, $\eta_p^2=0.52$], with children choosing real objects significantly more for accurate productions ($M=93\%$, $SD=1\%$, range 67%-100%) than for substitutions ($M=72\%$, $SD=5\%$, range 17%--100%). Furthermore, a significant main effect for Substitution Type was found [$F(1,19)=4.43$, $p=0.05$, $\eta_p^2=0.19$]. However, this main effect was qualified by a significant interaction between Word Type and Substitution Type [$F(1,19)=6.20$ $p=0.02$ $\eta_p^2=0.25$].

Four paired samples t-tests were conducted to investigate the differences for the proportion of real object selections between accurate productions and misarticulations. A Bonferroni correction for multiple comparisons yielded a critical p-value of 0.0125 for significance for each comparison. Recall that each real word was paired with two different displays; (1) the real object (e.g. leaf) and the nonobject from the common substitute condition (e.g. nonobject75); (2) the real object (e.g., leaf) and the nonobject from the uncommon substitute condition (e.g., nonobject31). As expected, preschoolers chose real objects equally as often with accurate productions matched with common misarticulation visual displays ($M=92\%$, $SD=8\%$, range 75%-100%) as accurate productions matched with uncommon misarticulation visual displays ($M=94\%$, $SD=9\%$, range 67%-100%) [$t(19)= -0.77$, $p=0.45$]. In contrast, children chose real objects significantly more with accurate productions ($M=92\%$, $SD=8\%$, range 75%-100%) than with common misarticulations ($M=78\%$, $SD=22\%$, range 17%--100%) [$t(19) = 3.68$,

$p = 0.002$]. Likewise, children chose real objects significantly more when hearing accurate productions ($M = 94\%$, $SD = 9\%$) than when hearing words with uncommon misarticulations ($M=66\%$, $SD=28\%$) [$t(19)=4.26$, $p<.001$]. Finally, children chose real objects significantly more with common substitutes ($M = 78\%$, $SD = 22\%$) than with uncommon substitutes ($M = 66\%$, $SD=28\%$), [$t(19)=2.77$, $p = 0.012$]. This finding suggests that children’s identification of real objects was impacted by the commonness of the substitution type.

INSERT FIGURE 3 HERE

Findings associated with mean reaction time and area under the curve are shown in Figure 3. Mean reaction time (left chart) was compared using a 2 Word Type (Accurate vs. Substitute) x 2 Substitute Type (Common vs. Uncommon) repeated measures ANOVA. A significant main effect of Word Type (Accurate vs. Substitute) was found [$F(1,19)=30.61$, $p<.001$, $\eta_p^2=0.62$]. Children responded more quickly to accurate productions ($M=3250$, $SD=942$, range 1814--6196) than to misarticulated productions ($M=3883$, $SD=1246$, range 1866–7544) and this was apparent for both the common and uncommon visual displays and substitutes, as shown in Figure 3. A significant main effect of Substitute Type was found [$F(1,19)=4.60$, $p<0.05$, $\eta_p^2=0.20$]. Children responded to words faster in the common condition ($M=3741$, $SD=1083$, range 1807-6192) than in the uncommon condition ($M=4024$, $SD=1409$, range 2257-7983). No significant interaction between Word Type and Substitution Type was observed [$F(1,19)=0.44$, $p=0.51$, $\eta_p^2=0.02$]. There was no significant interaction, so post-hoc testing was not conducted.

Area under the curve (AUC) was also compared using a 2 Word Type (Accurate vs. Substitute) x 2 Substitute Type (Common vs. Uncommon) repeated measures ANOVA (see

Figure 3, right chart). A significant main effect for Word Type was found [$F(1,19)=5.11, p=0.04, \eta_p^2=0.21$]. These results indicated that the AUC was significantly lower on accurate word trials (Figure 3, right chart, dark bars) ($M=0.8, SD=0.16$, range 0.003--2.65) than on trials containing substitutions (Figure 3, right chart, light bars) ($M=1.03, SD=0.21$, range -0.40--4.66). This finding indicates that the mouse trajectory for accurately produced words was more direct than for misarticulated words. No significant main effect of Substitute Type was found [$F(1,19)=0.13, p=0.73, \eta_p^2=0.01$]. Moreover, no significant interaction between Word Type and Substitution Type was observed [$F(1,19)=0.12, p=0.73, \eta_p^2=0.01$]. Since no significant interaction between Word Type and Substitution Type was observed, post-hoc testing was not conducted.

Experiment 1 Discussion

The results of Experiment 1 showed that children overwhelmingly chose real objects over nonobjects, which is a finding consistent with Creel (2012). These responses suggest that children were generally tolerant of variability in recognizing words. However, children clearly differentiated accurate and misarticulated productions. Specifically, children chose real objects more often, more quickly and with more direct mouse trajectories for accurate productions than for misarticulated productions. This finding is consistent with the findings of Creel (2012). Furthermore, children were sensitive to whether the misarticulated production was one that they potentially had heard before, as opposed to one that they likely had not heard before. Children selected more real objects for words with common misarticulations than uncommon misarticulations. This extends the work of Creel by showing that children's experience with substitution commonness influences their responding, and parallels findings from adults showing that having experience with a variety of different dialects influences responding (Clopper & Pisoni, 2004). In Experiment 1, no difference between common and uncommon was found for

1
2
3 reaction time and AUC, suggesting that the commonness of the substitute does not support
4
5 children in making selections more decisively.
6
7

8
9 The apparent bias toward selecting real objects may be the result of other untested
10
11 linguistic factors, rather than an inherent draw toward choosing real objects over novel objects.
12
13 In adult speech, the fundamental frequency (F0) is lower than that of a child. This supralinguistic
14
15 factor may influence children's processing because it is rare to hear an adult produce
16
17 misarticulations. Furthermore, children's processing may be slowed as a result of this exact point,
18
19 but viewed through a sociolinguistic lens: adults do not tend to produce misarticulations. In
20
21 addition to supralinguistic and sociolinguistic factors, we also considered the possibility that
22
23 children attend to covert contrasts that children produce in typical phonological development.
24
25 Covert contrasts are subphonemic contrasts produced by children who are learning new sounds
26
27 (Scobbie, Gibbon & Hardcastle, 2000). The productions fall within the typical acoustic values
28
29 for the sound (e.g., /w/) but the acoustic values for the sound produced as target ([w] for /w/ in
30
31 white) may consistently differ from the acoustic values for the sound produced as a substitute
32
33 ([w] for /r/ in right). In fact, in some cases, adults can perceptually distinguish the two different
34
35 productions. Thus, in naturally produced misarticulations, there may be covert acoustic cues
36
37 present to indicate whether a child's production should be interpreted as being a misarticulated
38
39 production of a target word. Moreover, this covert cue could facilitate processing of
40
41 misarticulated productions leading to more real object selections, as well as faster and more
42
43 direct real object selections for misarticulated words. These cues would likely not be present
44
45 when an adult is recording a list of real words and nonwords. Therefore, Experiment 2 used
46
47 naturalistic misarticulations from children with speech sound disorders to determine whether this
48
49 would decrease the difference between accurately produced and misarticulated productions.

Experiment 2

Experiment 2 contained accurate and misarticulated stimuli produced by children. Since uncommon substitutes are rare in typically-developing speech, only commonly produced substitutes and accurately produced words were used as stimuli in this experiment.

- 1) Do children select real objects more often than nonobjects for accurately produced words than words containing common substitutions?
- 2) Do children select the real objects for accurately produced words more quickly and with more direct mouse trajectories than real objects for commonly misarticulated words?

Participants

Participants were 17 monolingual children recruited from local preschools. Fourteen children were Caucasian, 1 child was Multiracial, 1 child was Native American, and 1 child was African American. Two were excluded from participation due to failing hearing screenings, one was excluded for scoring too low on the GFTA-2. Therefore, 14 monolingual preschoolers (aged $M=4$ years, 6 months, $SD=6$ months, range 3 years, 11 months – 5 years, 4 months) were included in the experimental protocol. As in Experiment 1, parents rated their children's exposure to misarticulating children using a visual analog scale. From a possible 0 to 100 scale, parents rated their children's exposure to misarticulating children to be 47 ($SD=24$, range 11-79). These children were typical in terms of standard scores on receptive vocabulary (PPVT-4; $M=114$, $SD=11$, range 88-129) and articulation (GFTA-2; $M=113$, $SD=8$, range 95-122), and passed a hearing screening at 20 dB for 1000, 2000 and 4000 Hz.

Materials

Auditory Stimuli. Stimuli were selected from recordings taken in previous studies, unrelated to the present research (Storkel & Hoover, 2010; Storkel, Maekawa, & Hoover, 2010).

These stimuli were produced by multiple children, because no single child produced each of the common misarticulations needed, and because typical productions were required as well for the accurate condition. Due to the rarity of uncommon substitutions in typical phonological development, only words containing common substitutions, and accurate child-productions of words were taken from the recordings and used as stimuli in Experiment 2. These misarticulations were produced by children with phonological disorders, who produced natural misarticulations in a speech probe. Since words were taken from existing recordings, the words from Experiment 1 could not be replicated. Therefore, each of the words in Experiment 2 were different from those used in Experiment 1 (see Table 4, Supplemental Materials). Recordings were edited in Praat to 65 dB scale peak intensity, and to include a 500ms interstimulus interval, just as in Experiment 1.

Auditory Stimuli. Visual stimuli were selected through the same methods as in Experiment 1. Where the same pictures could be used, they were. For words not included in Experiment 1, real object pictures were selected from the same databases in Experiment 1. Nonobjects were the same as Experiment 1. Since there were no uncommon substitutes in this experiment, only 12 nonobject pictures were required. These were selected and assigned in the same manner as in Experiment 1.

Experimental Design

The experimental design was counterbalanced in the same way as Experiment 1, except there were half as many versions since there was no uncommon substitute for which to control.

Procedures

Experimental procedures and technology were the same as Experiment 1.

Data Analysis

The dependent variables were the same as Experiment 1, but the independent variables were reduced to only accurate productions versus common misarticulations. The differences between accurate and common misarticulations were analyzed using paired samples t-tests for each dependent variable.

Results

INSERT FIGURE 4 HERE

The proportion of real object selections were analyzed using a paired samples t-test (Accurate vs. Common substitution). The results revealed that children chose real objects significantly more when hearing accurate productions ($M = 93\%$ $SD=7\%$) than common substitutions ($M = 87\%$, $SD=8\%$) [$t(13)=-2.75$, $p=0.02$].

INSERT FIGURE 5 HERE

Reaction time on real object selections were shown in the left panel of Figure 5 and were analyzed using a paired samples t-test (Accurate vs. Common substitution). The results of this comparison showed that children chose real objects significantly faster when hearing accurate productions ($M= 4437$, $SD=1207$) than when hearing common misarticulations ($M= 5137$, $SD=1237$) [$t(13)=2.17$, $p=0.05$].

In terms of mouse trajectory (see right panel of Figure 5), children's responses reflected the same pattern as the accuracy and reaction time data. Children's mouse movements were more direct when hearing accurate productions ($M=0.50$, $SD=0.34$) than common substitutions ($M=0.97$, $SD=0.98$) [$t(13)=2.52$, $p=0.03$].

Experiment 2 Discussion

The results of the present study mirrored those of Experiment 1, and were consistent with findings from Creel (2012). Preschoolers identified words containing speech sound substitutions

as real objects a large proportion of the time, but experienced slower processing in the presence of misarticulations. These results suggest that misarticulations influence children's identification and processing of words, not spectral or sociolinguistic factors associated with the incongruence of hearing misarticulations found in adult speech. Using naturally misarticulated speech did not provide additional subphonemic cues that facilitated processing. Therefore, if covert contrasts in the common condition were present, there was no apparent facilitation in terms of real object selection, because the difference between the accurate and common conditions remained the same as the difference found in Experiment 1. Thus, regardless of whether words were produced by a child or an adult, children selected more real objects, more quickly, and with more direct mouse trajectories for accurate productions than for misarticulated productions.

Previous research using MouseTracker has shown that, in adults, this technology can mirror the results of eye-tracking technology by measuring continuous streams of hand movement (Freeman, Dale, & Farmer, 2011; Magnuson, 2005). However, the present study was one of the first to use hand tracking with children in a psycholinguistic paradigm. Since the validity of hand tracking in children has not been empirically tested, and previous research, such as Creel (2012) used eye-tracking, it was important to replicate the present study using eye-tracking to test our results against an established measurement tool. One particular area of concern was the large amount of variability in the mouse trajectory for the area under the curve measurements in each experiment. These large standard deviations suggest that the mouse trajectory component of these results may not be as sensitive as eye gaze. Although differences between common and uncommon misarticulation conditions were not detected using this measurement, it is possible that difference do exist, and these may be revealed by measuring variability more precisely through the use of children's eye gaze. Since Experiments 1 and 2

showed a delay in reaction time for all substitutes, the analysis of children's gaze over time may reveal what occurs during this delay, and show if there were any behavioral differences during this delay that would account for the differences within substitution types found in accuracy data.

Experiment 3

The purpose of Experiment 3 was to replicate Experiment 1 as closely as possible in order to draw a comparison between the two technological methods, and to examine children's on-line processing of misarticulated words. Experiment 3 addressed the following questions:

- 1) Do children look to real objects more than novel objects in the presence of accurate productions of words than in the presence of misarticulated productions of words?
- 2) When words are misarticulated, do children look to real objects more in the presence of common substitutions than in uncommon substitutions?

Procedures

Participants

Participants were 24 monolingual English-speaking preschoolers (age $M=5$ years, 0 months, $SD=6$ months, range 4 years, 0 months -5 years, 9 months) recruited through word-of-mouth and flyers distributed at local preschools. Sixteen were male and 8 were female. Twenty children were Caucasian, 1 child was African American, 1 child was Native American, 1 child was Asian or Pacific Islander, and 1 child was of undisclosed heritage. Of these, 9 were excluded from analysis: 7 due to calibration failure, 1 due to having a previous diagnosis, and 1 due to scoring below the 16th percentile on the GFTA-2. Parents rated their children's exposure to misarticulations as 54 on average ($SD=24$, range 15 to 100). Participants all passed a pure-tone threshold hearing screening at 20 dB HL for 1000, 2000 and 4000 Hz, binaurally. Participants were typical in terms of receptive vocabulary as measured by the PPVT-4, with standard scores

falling within the expected range of 85-115 ($M=119$, $SD=12$, range 97-142), and typical in terms of articulation as measured by the GFTA-2, with all standard scores falling within the range of 85-115 ($M=105$, $SD=9$, range 89-117). Parental consent and child assent were obtained in the same manners as in Experiments 1 and 2.

Materials

Auditory Stimuli. Stimuli were the same as used in Experiment 1. The adult productions were selected for Experiment 3 because they were recorded in an anechoic chamber, the words were more carefully controlled in terms of frequency, feature difference and duration (see Table 1 and see Table 1, Supplemental Materials). Furthermore, the differences between common and uncommon substitutions could be explored. Since no significant difference was identified between Experiment 2 and Experiment 1, the adult-recorded stimuli were deemed acceptable for further use in Experiment 3. In Experiments 1 and 2, 250 ms of silence were embedded at the beginning and end of the sound files. To ensure that a full visual scan of the display was allowed, 500 ms of silence were inserted prior to the presentation of each word in accordance with the methods of Creel (2012). As in Experiments 1 and 2, preschoolers heard stimulus words over external speakers.

Visual Stimuli. Visual stimuli were the same as in Experiment 1 in that the two stimulus pictures were located at each top corner of the display; however, in place of a “start” button, children’s gaze initiated the trial by fixating on a centralized cross. Typical visual world paradigms employ the use of distractor pictures and arrays of 4 or more objects (Allopenna, Magnuson, & Tanenhaus, 1998; Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995). These include objects related to the stimulus, as well as filler items. This provides competitors that subjects must ignore in order to arrive at the targeted object. However, since replication was

the key motivator for conducting Experiment 3, the simple array of one nonobject and one real object was used for this study. Therefore, our areas of measurement for eye gaze were limited to the upper right and left-hand corners of the screen.

Experimental Procedures

Children were tested using an Eyelink 1000 (SR Research) arm-mounted LCD eye-tracker in a dedicated lab. The experiment was designed using Experiment Builder Software (SR Research) to mirror the design of Experiment 1. After speech-language evaluations and hearing screening were conducted, children were seated in front of a computer, and a “target” sticker was placed on their forehead to allow for location of the eye by the eye-tracker. Then children underwent a calibration procedure that varied from 5 to 7 minutes before beginning the experimental trials. The calibration procedure was a manual 9-point grid calibration and validation on a 1024 x 768 resolution 17-inch LCD display. Children were required to fixate on each of these 9 points as they appeared, one at a time, at regular locations across the monitor screen. Fixations were required to occur twice at each location (once for identification, once for validation) before the experimental protocol was initiated. Once the experiment began, children were required to fixate on a cross in the center of the screen for 1000 ms to initiate each trial. This cross was the same visual cross that was used for calibration, and served as a drift correction point before each trial. Visual stimuli were presented for 500 ms to allow for a visual scan prior to the presentation of the auditory stimuli.

As in Experiments 1 and 2, children were provided with 5 practice trials to assimilate them with the experimental procedure. Unlike the previous experiments, responses were recorded using a button box. Children were asked to press the left-hand button to select the left-hand picture on the display, and to press the right-hand button to select the right-hand picture on

the display. A button box was used instead of a mouse for this experiment because the purpose of Experiment 3 was to determine if there was a difference in children’s processing within substitution types. Since processing measures were taken through eye-gaze, we did not want to risk data loss by using a mouse, which may cause children to look down at their hand in order to respond. The button box reduced the likelihood that children would look to their hands, because they rested each hand on a button, and no movement was required. Since the purpose of Experiment 3 was to examine children’s eye-gaze behavior in response to misarticulations, the results of the button box data are included in the Supplemental Materials. Furthermore, methodological considerations between Mousetracker and Eye-tracking with a button box are discussed in the Supplemental Materials.

All other procedures (evaluations, feedback, counterbalancing) are the same as Experiment 1.

Data Analysis

Time-course eye-gaze fixations were analyzed on all trials to examine children’s eye-gazes as the word unfolds; this measure was in contrast to the AUC measures reported in Experiments 1 and 2. The average duration of the initial phoneme, the word offset, and the average response time were identified and coded into the experiment as variables which allowed for an examination of these windows of time. In accordance with typical conventions in visual world paradigm studies, the time windows were shifted 200 ms to account for the initiation of eye movements (Hallett, 1986). Data were extracted and processed using Data Viewer software (SR Research) package. Once data were processed, the results were binned in 20 ms intervals to prepare for analysis.

Results

Results of real object selections and reaction time are located in the supplemental materials. Here, we focused exclusively on analysis of eye-gaze to address the research questions.

INSERT FIGURE 6 HERE

Children's proportion of time-course fixations were analyzed by plotting the average of the mean proportion of fixations to target and novel objects in each condition (Figure 6). For each condition, the average offset of the initial phoneme, the average word offset, and the average response time, respectively, are demarcated at time points along the x-axis, identifying the time at which these events occurred on average (in milliseconds), and shifted 200ms to allow for the initiation of the eye movement as described above. These time windows were selected because they may reveal at what point during the trials children identify words as being accurate or misarticulated, and therefore may reveal more about children's processing of these words by allowing for the identification of how long it took for children to make a statistically meaningful decision about the words they heard. A 3 Word Type (Accurate, Common, Uncommon) by 2 Picture Type Looks (Real Object vs. Nonobject) repeated measures ANOVA was conducted for each of the three time windows.

In the initial phoneme window, a significant main effect of Picture Type Looks was found [$F(1,6)=200.46, p<0.001, \eta_p^2=0.97$], where participants across conditions looked to real objects significantly less ($M=21\%, SD=12\%$) than nonobjects ($M=29\%, SD=16\%$). No significant effect of Word Type was found [$F(2,12)=0.71, p=0.43, \eta_p^2=0.11$], and the interaction between Word Type and Picture Type Looks was nonsignificant [$F(2,12)=1.12, p=0.33, \eta_p^2=0.16$]. For Picture Type looks, a planned post-hoc paired samples t-test revealed that within the time window of the initial phoneme, children fixated on nonobjects significantly more than

1
2
3 real objects in each condition: accurate [$t(6)=-14.16, p<0.001$, common [$t(6)=-25.24, p<0.001$],
4
5 and [$t(6)=-7.93, p<0.001$] uncommon. This finding was likely due to the novelty of the
6
7 nonobjects, thus yielding a longer initial fixation on these pictures than real objects.
8
9

10 In the time window (central window, Figure 6) spanning the offset of the initial phoneme
11
12 to the word offset (encompassing the rime), a significant interaction between Word Type and
13
14 Picture Type Looks was found [$F(2,38)=17.32, p<0.001, \eta_p^2=0.48$]. Furthermore the main effects
15
16 of Word Type [$F(2,38)=84.50, p<0.001, \eta_p^2=0.82$] and Picture Type Looks [$F(1,19)=5.34,$
17
18 $p=0.03, \eta_p^2=0.22$] were statistically significant. Planned post-hoc paired samples t-tests were
19
20 conducted to evaluate the comparisons that may be causing the interaction between Word Type
21
22 and Picture Type Looks. As seen in the top panel of Figure 6, in accurate conditions, children
23
24 looked to real objects significantly more in this time window ($M=26\%, SD=3\%$) than nonobjects
25
26 ($M=24\%, SD=2.6\%$) [$t(19)=2.31, p=0.03$]. In contrast, in the common misarticulation conditions
27
28 (middle panel of Figure 6), the proportion of looks between real objects ($M=25\%, SD=2\%$) was
29
30 not significantly different from the proportion of looks to nonobjects ($M=24\%, SD=1.9\%$)
31
32 [$t(19)=0.76, p=0.46$]. Finally, in uncommon conditions (bottom panel of Figure 6), children
33
34 looked at real objects significantly more ($M=28\%, SD=3\%$) than nonobjects ($M=24\%, SD=3\%$)
35
36 [$t(19)=2.97, p=0.01$]. The results of these comparisons showed that the interaction was driven by
37
38 differences in the behavior observed in the accurate and uncommon conditions compared to the
39
40 common misarticulation condition. In terms of their selections, recall that children chose real
41
42 objects more than novel objects across conditions, but appear to do so in this time window for the
43
44 accurate condition, but remain undecided for the common condition (no effect). In terms of the
45
46 uncommon condition (Figure 6, bottom panel), looking behavior was similar to what was
47
48 observed in the accurate production condition, but converse to the selection results. It is possible
49
50
51
52
53
54
55
56
57
58
59
60

that, since the uncommon reaction time was much longer than that of the accurate condition--from phoneme offset to word offset--children were, at this point, considering the real object as a possibility for the uncommon misarticulation. In fact, they ultimately made this selection in the majority of trials; they did, however, take longer to do so, as suggested by the response time and eye fixation results.

Within the time window spanning the average word offset through the average response time (final time window, Figure 6), a significant interaction between Word Type and Picture Type Looks was observed [$F(2,88)=142.80, p<0.001, \eta_p^2=0.76$]. Additionally, significant main effects of Word Type [$F(2,88)=16.50, p<0.001, \eta_p^2=0.27$] and Picture Type Looks [$F(1,44)=22.73, p<0.001, \eta_p^2=0.34$] were found. Planned post-hoc t-tests were conducted to further examine the influential factors associated with the significant interaction between Word Type and Picture Type Looks. In accurate conditions (Figure 6, top), children looked to real objects significantly more ($M=21\%, SD=7\%$) than nonobjects ($M=18\%, SD=3\%$) [$t(45)=4.74, p<0.001$]. Also, children selected the real object on the majority of trials in this condition ($M=78\%, SD=20\%$). In common misarticulation conditions (Figure 6, center panel), children looked to real objects ($M=20\%, SD=7\%$) about the same as novel objects ($M=22\%, SD=3\%$) [$t(45)=-1.86, p=0.07$] but they tended to select the real object on the majority of trials ($M=67\%, SD=24\%$). In uncommon misarticulation conditions (Figure 6, bottom), children looked to real objects significantly more ($M=24\%, SD=7\%$) than nonobjects ($M=13\%, SD=4.3\%$) [$t(45)=17.78, p<0.001$]. However, toward the end of the time-window, through a visual inspection of the bottom panel, children's eye fixation appears to return to the nonobject. Interestingly, children selected the real object ($M=58\%, SD=23\%$) only slightly more frequently than the nonobject. Therefore, this "jump" in fixation to the nonobject may be the result of children "checking back"

1
2
3 toward the nonobject before making their selection on longer trials, and a result of the high level
4
5 of variability in this condition. The results of these comparisons revealed that the interaction was
6
7 the result of significant differences in accurate and uncommon conditions compared to common
8
9 misarticulation conditions.
10
11

12
13 During the initial time window, children appeared to be examining the visual display in a
14
15 similar manner regardless of the auditory stimuli. That is, children focused on the more salient
16
17 novel object rather than the familiar real object. For the remaining two time windows, children
18
19 began to focus differentially on the visual display based on the auditory stimuli heard. For the
20
21 accurate and uncommon misarticulation conditions, children focused more on the real object
22
23 than the novel object. For the common misarticulation condition, children looked back and forth
24
25 between both objects.
26
27
28

29
30 Overall, the proportion of looks found in these results was quite low as compared with
31
32 previous eye-tracking studies. Since we intended to replicate our findings from Experiments 1
33
34 and 2, we only used 2 pictures, rather than the traditional array of 4. Therefore, this limits our
35
36 measurements to only two areas of interest in the upper right and left corners of the screen. If
37
38 children looked elsewhere on the screen or offscreen, their gazes were not included in the
39
40 statistical analysis for Experiment 3. However, we calculated the overall proportion of looks to
41
42 other areas of the screen (“on-screen elsewhere”) and proportion of looks to the hands or
43
44 blinking (“off-screen”) to determine whether children’s lowered accuracy and low proportion of
45
46 looks to the areas of interest were potentially related. This calculation was conducted because it
47
48 explains the nature of children’s eye-gaze behavior and provides insight into behavioral factors
49
50 that contributed to the findings of Experiment 3. In the accurate condition, across the entire time
51
52 window, children looked “on-screen elsewhere” 63% of the time ($SD=9\%$, range 45%-79%), and
53
54
55
56
57
58
59
60

to the hands or blinking (off-screen) 19% of the time ($SD=15\%$, range 2%-53%). In the common misarticulation condition, across the entire time window, children looked “on-screen elsewhere” 60% of the time ($SD=7\%$, range 51%-75%), and off-screen 19% of the time ($SD=12\%$, range 0%-40%). In the uncommon misarticulation condition, across the entire time window, children looked “on-screen elsewhere” 58% of the time ($SD=10\%$, range 43%-73%), and off-screen 23% of the time ($SD=15\%$, range 4%-56%). These findings suggest that children spent approximately 20% of the time looking to their hands, and the range of off-screen looks was quite high. This heightened level of variability between subjects was consistent with the accuracy and reaction time findings for Experiment 3 (Supplemental Materials).

Experiment 3 Discussion

The results of Experiment 3 confirmed the results of Experiments 1 and 2: preschoolers identified and processed words with misarticulations differently than those that were accurately produced. When hearing accurate productions, children selected the real object on the majority of trials and tended to look more at the real object during presentation of the rime and during the post-stimulus window. This suggests that they quickly and efficiently identified the referent and were confident in their choice. In contrast, when hearing the common misarticulation, children selected real objects on the majority of trials but looked equally at the real object and the nonobject, suggesting that they were uncertain of their interpretation of the word. Finally, in the uncommon misarticulation condition, children selected the real object almost as frequently as the selected the nonobject. Interestingly, they tended to look at the real object more frequently than the nonobject, suggesting that, regardless of which object they selected (real object 58% of responses vs. nonobject 42% of responses), their selection was less certain and they were still considering whether the real object was a viable alternative to the nonobject, perhaps due to the

1
2
3 rime and final consonant matching that of the real object referent.
4

5 An additional purpose of Experiment 3 was to examine the similarities in processing
6 measures between MouseTracker and eye-tracking. Our results suggest that MouseTracker is an
7 appropriate tool for use with preschool children, and more easily implemented due to the low
8 cost, portability of the equipment, and lack of calibration required. If reaction time and accuracy
9 data are the only desired measurements, then MouseTracker is a tool that is appropriate for
10 obtaining those. However, if more detailed information about moment-to-moment looking
11 behavior is required, eye-tracker provides a greater level of detail for that purpose.

22 **Discussion**
23

24 Overall, these results mirror the input that these children receive in terms of frequency.
25 Children hear accurate productions of words most frequently in their day-to-day lives.
26 Consequently, when children hear an accurate production, whether by an adult or a child, they
27 quickly select the real object referent. Although children hear misarticulated words less
28 frequently than accurate productions, they do hear common misarticulations. Thus, when they
29 hear a common misarticulation, whether spoken by a child or an adult, they are willing to accept
30 it as a label for a real object, but they are slower and less certain of this pairing. Finally, children
31 rarely encounter uncommon substitutes. Therefore, when they hear an uncommon
32 misarticulation, produced by either an adult or a child, they are less willing to accept it as a label
33 for a real object, and are thus slower and more uncertain of their selection.

41
42
43
44
45
46
47

48 These results coincide with the findings of Creel (2012). In Creel (2012), children
49 identified words with a close feature distance as real objects significantly more than words that
50 were far. Furthermore, Creel (2012) observed slowed response times in the presence of any
51 phonemic substitution regardless of distance—a finding which is synonymous with the results of
52
53
54
55
56
57
58
59
60

1
2
3 the present study. Unlike Creel (2012), feature distance in the present study was controlled
4
5 between common and uncommon substitution conditions, and a difference was found in terms of
6
7 accuracy and in eye-gaze behavior. This finding suggests that, although children used feature
8
9 distance in previous studies (Creel, 2012) to determine if a word is known or novel, they must
10
11 additionally engage their own experience in making these judgments. This is especially true
12
13 when considering that responses to common misarticulations were different than uncommon
14
15 misarticulations, despite the control of feature distance.
16
17
18

19
20 Overall, children's reaction times were slowed in the presence of substitutions--a finding
21
22 that is consistent with those found in previous studies of both child (Creel, 2012), and adult
23
24 studies (Munro & Derwing, 1995). The results of processing measures in the present study
25
26 support the idea that children are sensitive to phonological information in their native language,
27
28 but they may be more flexible in their interpretation of the message. Although children are
29
30 slowed, they still retrieve an appropriate real-object to match with the variability, and draw upon
31
32 their knowledge of the likelihood of those phonemic differences. However, when paired with the
33
34 real object selection data, it appears that, despite the additional processing time needed,
35
36 children's representations of words are flexible and can accommodate variability without
37
38 destroying the message.
39
40
41
42

43
44 The findings of the present studies provide evidence for children's word-identification
45
46 behavior in a carefully controlled environment. This evidence would likely change in the context
47
48 of a real-world situation. In a preschool setting, for example, children are likely to have a
49
50 meaningful semantic context that would influence their judgment of words containing
51
52 misarticulations. Furthermore, the present study did not provide any forms of feedback. In a
53
54 social interaction, children receive feedback from their communication partners that would assist

in confirming or denying the listener’s understanding of the intended message. For example, if a child requests a toy using a speech sound substitution, and receives the wrong toy in response, there is likely to be additional interaction. Whether the child requests the toy again, replies “no,” or gets the targeted toy him or herself, the listener receives negative feedback and may revise their interpretation of the message for the next time. The results of the present study show that in the absence of semantic context, and in the absence of positive or negative feedback, children are largely able to understand speech sound variability and accept these phonemic substitutions as being variants of real words.

Conclusion

The results of the present study showed that children’s experience with common misarticulations positively impacted their word identification; however, processing measures, such as reaction time, were slowed as a result. Overall, the results of the present study coincided with previous research on children’s perception of speech variability (Creel, 2012), suggesting that at age 4-6, phonological representations of words in the mental lexicon are flexible enough to accommodate multiple phonological forms for a singular referent.

Figure Captions

Figure 1. Participants first see the "Start" screen (top). After clicking the "Start" button, the screen changed to present the object choices (bottom) and the auditory stimulus (e.g. "leaf" or "weaf"). Note that the actual pictures are not shown due to copyright.

Figure 2. Mean proportion of children's real objects selections when hearing accurate productions and common and uncommon substitutions.

Figure 3. Processing measures for Experiment 1. (Left) Mean reaction time for mouse-clicks by condition. (Right) Mean area under the curve for mouse trajectories. This measurement is the area of the sum of the lines created by all of the mouse trajectories by condition. Large values indicate a less direct mouse path and suggests more uncertainty in selection.

Figure 4: Mean proportion of children's real objects selections when hearing accurate productions and common and uncommon substitutions.

Figure 5. Processing measures for Experiment 2. (Left) Mean reaction time by condition with standard error bars for mouse-click responses. (Right) Mean area under the curve for mouse trajectories by stimulus condition.

Figure 6. Time-course fixations for each condition: accurate (top panel); common substitutions (middle panel) and uncommon substitutions (bottom panel). Initial phoneme offset (PO), word offset (WO) and average response time (RT) are indicated by the vertical bars and labels along the x-axis of each chart, respectively.

Acknowledgments

The first author was a doctoral trainee whose research was funded by a National Institute on Deafness and Other Communication Disorders training grant, #5 T32 DC000052-17. We would like to express our gratitude to the families who participated in this research, to the cooperating preschool sites, and to our research team.

Authors' Note

This research was conducted at the University of Kansas, as part of the requirements for the master's degree of the first author.

Note. Table 1 shows stimuli used in Experiment 1 and Experiment 3. Accurate words are written orthographically, and misarticulated words are transcribed using International Phonetic Association transcription conventions. The average duration of each token, as recorded by an adult native speaker of American English, is listed to the right of each word in milliseconds. Mean and standard deviations for each condition are listed beneath each column.

Max	16	0.20	5.7	Max	17	0.20	5.9

Note. Table 2 details the nonobject characteristics used as visual stimuli in Experiments 1-3. Nonobjects are from Kroll and Potter (1984). Each set is associated with one of two misarticulation types, and these are counterbalanced across versions of the study. “Strongest neighbor” is the highest neighborhood density of real words identified by children to associate with the nonobjects. Objectlikeness rating is a scalar rating of the objects “likeness” to real items. Mean, standard deviation and range are listed beneath each set to demonstrate that each set

was balanced. Each child saw all pictures twice, once with an accurate word, and once with a misarticulated word.

girl	Accurate(Common)	nobj13	girl	girl	Accurate(Uncommon)	girl	nobj59
dirl	Common	nobj13	girl	birl	Uncommon	girl	nobj59

Note. Table 3 demonstrates the counterbalancing of blocks and nonobjects. This is one version of the study. Across other versions, the items that are “Response Left” would be “Response Right” and those in Block 1 would be in Block 2 and vice versa to ensure that no bias towards or against choosing any real objects or sets of real objects was apparent. Trials within a block were randomized by the experimental control software.

<i>Max</i>		1310			1234

Note. Table 4 shows the stimuli used in Experiment 2. These were selected from previous recordings. Note that multiple child talkers with phonological disorders were used in both accurate and substitute conditions, and overall duration between the two conditions was controlled as closely as possible. Accurate words are written orthographically, and substitutes are transcribed using International Phonetic Association conventions.

Experiment 3: Button box procedures and results

Data Analysis

Accuracy and reaction time data were calculated in the same way as Experiment 1, but these data were calculated from the button box response method, rather than a mouse click as in Experiment 1.

Results

Figure 1

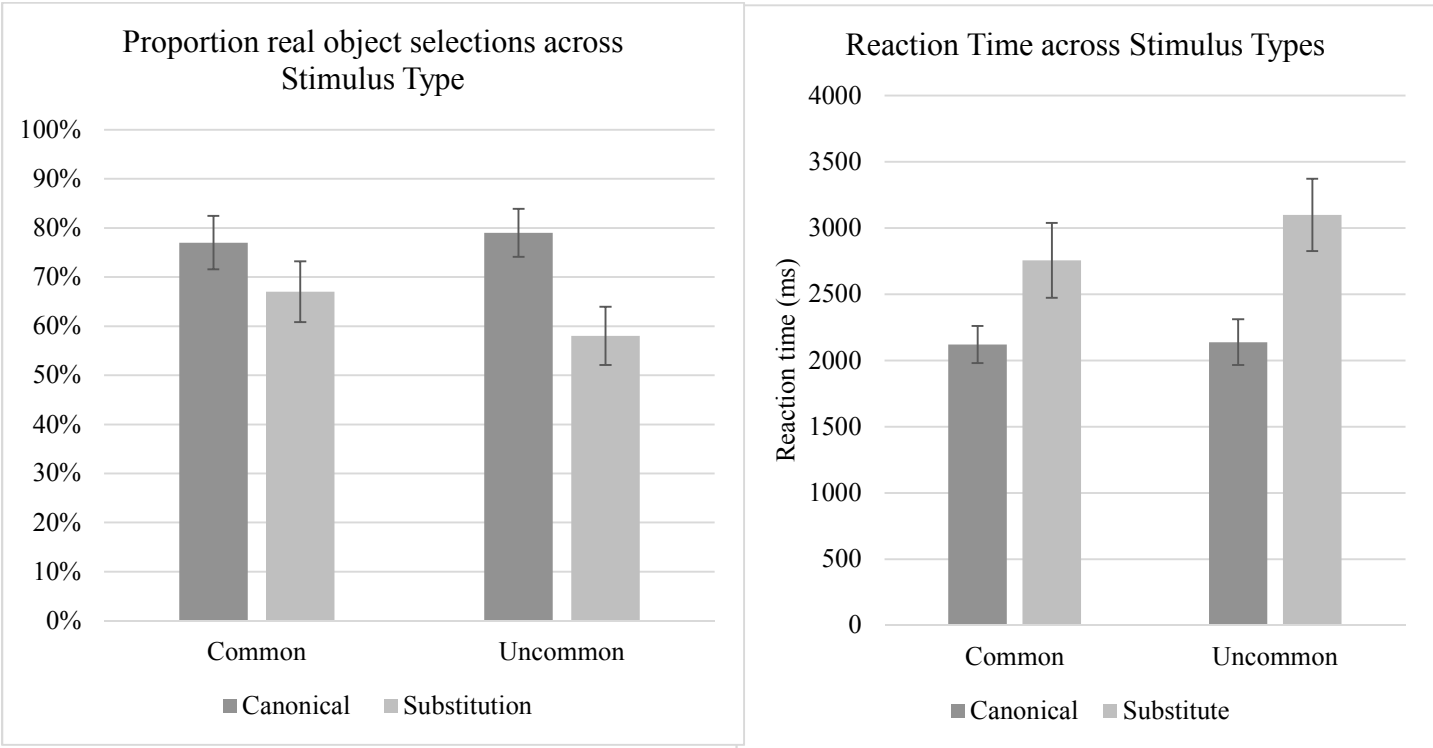

Figure 1. Mean proportion real object selections for button-box responses in Experiment 3(left). Mean reaction time for button-box responses across stimulus types for Experiment 3 (right).

The accuracy and reaction time results are displayed in Figure 1. In terms of accuracy (Figure 1, left), children chose real objects more for accurate productions than misarticulated productions, consistent with the results of Experiment 1 and Experiment 2. The proportion of real object selections were compared using a 2 Word Type (Accurate vs. Substitute) x 2 Substitute Type (Common vs. Uncommon) repeated measures ANOVA. The main effect of Word Type was significant [$F(1,14)=9.77$, $p<0.001$, $\eta_p^2=0.41$]. No significant main effect of

Substitute type was found [$F(1,14)=1.06, p=0.32, \eta_p^2=0.07$]. The interaction between Word Type and Substitution type was not statistically significant [$F(1,14)=4.05, p=0.06, \eta_p^2=0.22$].

Although the interaction was not statistically significant, we conducted post-hoc testing to result further examine similarities and differences between Experiment 1 and 3. We found no difference in real object selections between accurate productions ($M=76\%$) and common misarticulations ($M=67\%$) [$t(14)=1.09, p=0.09$], a finding that is inconsistent with results in Experiments 1 and 2. However, like Experiment 1 and Experiment 2, children chose real objects significantly more for accurate productions ($M=79\%$) than uncommon misarticulations ($M=58\%$) [$t(14)=3.54, p<0.001$]. Finally, real object selections for common misarticulations ($M=67\%$) were not significantly greater than uncommon misarticulations ($M=58\%$) [$t(14)=1.66, p=0.12$]. Recall that real object selections between common and uncommon misarticulation conditions were statistically significant in Experiment 1.

Mean reaction time (Figure 1, right) was compared using a 2 Word Type (Accurate vs. Substitute) x 2 Substitute Type (Common vs. Uncommon) repeated measures ANOVA. A significant main effect of Word Type (accurate vs. substitution) was found [$F(1,14)=32.77, p<0.001, \eta_p^2=0.70$]. A significant main effect of Substitute Type (common vs. uncommon) was found [$F(1,14)=5.04, p=0.04, \eta_p^2=.27$]. The interaction between Word Type and Substitute Type was not statistically significant [$F(1,14)=1.40, p=0.26, \eta_p^2=0.09$]. Planned post-hoc paired samples t-tests were conducted to investigate the differences between accurate productions and misarticulations (Bonferroni correction, $p<0.0125$). As in Experiment 1, Children chose real objects significantly faster when hearing accurate productions ($M=2120$) than common substitute productions ($M=2754$) [$t(14)=-3.39, p<0.01$], and chose real objects significantly faster when hearing accurate productions ($M=2137$) than uncommon substitute productions ($M=3098$)

[$t(14)=-4.68, p<0.001$]. Subjects did not choose real objects significantly faster within substitution conditions (Common ($M=2754$) vs. Uncommon ($M=3098$) [$t(14)=-1.76, p=.10$]). Each of these findings is consistent with what was found in Experiment 1.

Discussion

Children selected real objects significantly more in accurate conditions than substitution conditions. They chose real objects more in accurate conditions than uncommon misarticulation conditions, but not in the accurate vs. common misarticulation condition and not in the common vs. uncommon misarticulation comparison. These results are inconsistent with what was found in Experiments 1 and 2 where children consistently chose real objects significantly more for accurate productions than both misarticulation conditions. In terms of reaction time, much like the results of Experiment 1, children chose real objects significantly faster when hearing accurate productions than either common misarticulations or uncommon misarticulations. However, in accordance with previous findings, no reaction time difference between common and uncommon misarticulations was found. The lack of replication of Experiment 1 and 2 with Experiment 3 is likely a result of these analyses being underpowered due to low sample size. It is possible that with more subjects, and therefore more statistical power, the results may align more closely to the finding in our previous experiments. The results of this analysis trend in the same direction as previous findings in Experiments 1 and 2.

The difference in response method—mouse click vs. button box—produced a difference in the overall proportion of real object selections. Children selected real objects less frequently with the button box in Experiment 3 than with the mouse click in Experiments 1 and 2. For example, for correct articulations, children selected the real object on average 92-94% of the time in Experiments 1 and 2 but only 77-79% of the time in Experiment 3. This finding suggests

1
2
3 that children made more errors in object selection with the button box (in Experiment 3) than
4
5 with the mouse (in Experiment 1-2). Although the button mapping appears straightforward (i.e.,
6
7 left-picture = left button; right picture = right button), these results suggest that children find
8
9 mouse-clicking a more natural and intuitive method for selecting pictures than a button press.
10
11 Therefore, where accuracy is of key relevance, a mouse-click response is an appropriate method
12
13 for preschoolers, because there is a visual component that allows the child to check their
14
15 response with the location of the cursor on the actual item to be selected.
16
17
18

19
20 However, if processing, such as response time, is of key importance, the length of time
21
22 required to make a selection with a mouse may mask response time differences in preschool-
23
24 aged children. Note that the reaction times in Experiment 3 with the button press were much
25
26 shorter than in Experiments 1 and 2 with the mouse movement and mouse click. Likewise, as
27
28 discussed in the main text of the article, eye-gaze results were the most sensitive measure for
29
30 detecting processing differences between common and uncommon misarticulation conditions as
31
32 opposed to mouse trajectory. Although the method for selecting objects may be clearer with
33
34 mouse tracking, children's agility in moving the mouse may not be developed enough to support
35
36 the use of mouse tracking as a precise method for measuring reaction time and response
37
38 trajectory.
